Abstract

In mammalian ovarian follicles, follicle stimulating hormone (FSH) and luteinizing hormone (LH) signal primarily through the G-protein G\(_{s}\) to elevate cAMP, but both of these hormones can also elevate Ca\(^{2+}\) under some conditions. Here, we investigate FSH- and LH-induced Ca\(^{2+}\) signaling in intact follicles of mice expressing genetically encoded Ca\(^{2+}\) sensors, Twitch-2B and GCaMP6s. At a physiological concentration (1 nM), FSH elevates Ca\(^{2+}\) within the granulosa cells of preantral and antral follicles. The Ca\(^{2+}\) rise begins several minutes after FSH application, peaks at \(~10\) min, remains above baseline for another \(~10\) min, and depends on extracellular Ca\(^{2+}\). However, suppression of the FSH-induced Ca\(^{2+}\) increase by reducing extracellular Ca\(^{2+}\) does not inhibit FSH-induced phosphorylation of MAP kinase, estradiol production, or the acquisition of LH responsiveness. Like FSH, LH also increases Ca\(^{2+}\), when applied to preovulatory follicles. At a physiological concentration (10 nM), LH elicits Ca\(^{2+}\) oscillations in a subset of cells in the outer mural granulosa layer. These oscillations continue for at least 6 h and depend on the activity of G\(_{q}\) family G-proteins. Suppression of the oscillations by G\(_{q}\) inhibition does not inhibit meiotic resumption, but does delay the time to 50% ovulation by about 3 h. In summary, both FSH and LH increase Ca\(^{2+}\) in the granulosa cells of intact follicles, but the functions of these Ca\(^{2+}\) rises are only starting to be identified.
**Summary Sentence**

Both FSH and LH increase Ca\(^{2+}\) in the granulosa cells of intact ovarian follicles from mice expressing genetically encoded sensors.

**Key words:** calcium, follicle, follicle-stimulating hormone, gonadotropins, granulosa cells, luteinizing hormone.

**Introduction**

In mammals, the G-protein coupled receptors for follicle stimulating hormone (FSH) and luteinizing hormone (LH) mediate events that lead to ovulation of fertilizable eggs. FSH receptors are expressed in granulosa cells of all follicles between the primary and preovulatory stages [1] and mediate the action of FSH to induce granulosa cell proliferation and differentiation, steroidogenesis, and LH receptor expression [2]. LH then acts on its receptors on the mural granulosa cells of preovulatory follicles, leading to oocyte maturation and ovulation [2, 3].

Both FSH and LH stimulate the G\(_\text{i}/\text{cAMP/protein kinase A (PKA)}\) pathway [2], and pharmacological activation of this pathway is, with a few exceptions, sufficient to fully mimic responses to FSH [1, 2, 4] and LH [2, 5–7]. Correspondingly, many of the FSH- and LH-stimulated responses are inhibited by inhibition of PKA [1, 2], although non-specificity of some commonly used PKA inhibitors [8] leaves open the question of whether FSH and LH signaling through non-PKA pathways may also be important. In addition to stimulating cAMP production, FSH increases intracellular Ca\(^{2+}\) in isolated porcine granulosa cells [9, 10], but not in a rat granulosa cell line [11]. LH signaling elevates Ca\(^{2+}\) in isolated porcine granulosa cells [12], and in luteinized human granulosa cells [13, 14], although not in isolated mouse granulosa cells [15].

These reports raise questions about whether FSH and LH also elevate Ca\(^{2+}\) in other species, and in intact follicles, and what functions such Ca\(^{2+}\) rises might have in follicular development. Previous studies have suggested possible roles for Ca\(^{2+}\) in the FSH-stimulated MAP kinase activation that contributes to estrogen synthesis [16, 17], and in LH-stimulated meiotic resumption [18, 19]. We chose to investigate these questions using intact follicles, because although many granulosa cell signaling pathways are similar in isolated cells and in intact follicles [2], some are not. For example, in intact follicles, LH causes a decrease in cyclic GMP to a few percent of the basal level [6, 20], whereas in isolated granulosa cells, this decrease fails to occur [21] or occurs only partially [22].

Although AM-ester-based Ca\(^{2+}\) indicators have been useful for investigating Ca\(^{2+}\) dynamics in isolated granulosa cells [9, 10, 12] and isolated oocytes [23, 24], their poor permeation into multilayer tissues precludes their use in isolated follicles. Mice expressing an early generation genetically encoded sensor, TN-XXL [25], had insufficient sensitivity to be useful (our unpublished results), but recently, mice expressing high-affinity optical sensors for Ca\(^{2+}\) have been developed [26, 27]. Using mouse lines expressing the sensors Twitch-2B and GCaMP6s, we show that FSH and LH both elevate Ca\(^{2+}\) in the granulosa cells of intact follicles. We also begin to investigate the physiological functions of the FSH- and LH-induced Ca\(^{2+}\) rises.

**Materials and methods**

**Mice**

Mice globally expressing the Twitch-2B Ca\(^{2+}\) sensor [28] were generated at Baylor College of Medicine, using CRISPR/CAS9 technology to target a Cre recombinase-responsive conditional Twitch-2B expression cassette containing the CAG promoter into the Rosa 26 locus. CRISPR/CAS9 and donor sequences were delivered by pronuclear injection into fertilized donor oocytes and implanted into pseudopregnant females. The mice were authenticated by isolating DNA from the founder and from F1 pups, followed by PCR and Southern blot using primers spanning the 3’ or 5’ insert junctions. To generate globally expressing Twitch-2B mice, conditional mice were bred to a Bact-Cre line to permanently delete the LoxP flanked stop cassette and establish a globally expressing sublineage. The mouse line was maintained on a C57BL/6J background.

Measurements were made using homzygotes expressing two copies of the Twitch-2B transgene or with heterozygotes expressing one copy. The concentration of Twitch-2B in the homozygote follicle cytoplasm was estimated to be ~20 μM, based on western blotting (Supplementary Figure S1A, see methods below), and an estimated cytoplasmic volume per follicle of 20 nl [29]. The mice had normal appearance and were fertile, and follicle-enclosed oocytes from these mice showed a normal time course of nuclear envelope breakdown (NEBD) and ovulated in response to LH (Supplementary Figure S1B), indicating that the sensor did not perturb physiological function.

Mice that express the GCaMP6s Ca\(^{2+}\) sensor Cre-dependently by way of a floxed stop cassette [27] were obtained from The Jackson Laboratory (Bar Harbor, ME; stock number 02 4106; B6;129S6/J strain). To induce global GCaMP6s expression, these mice were bred with Hprt-Cre mice [30] that were originally obtained from The Jackson Laboratory (stock number 0 04302), and that had been backcrossed onto a C57BL/6J background. The resulting line was maintained on a C57BL/6J background. Measurements were made using mice heterozygous for GCaMP6s. These mice had normal appearance and were fertile.

Genotyping of both Ca\(^{2+}\) sensor lines was accomplished by observing the fluorescence of ears and tails using goggles fitted with FHS/EF-3GY1 emission filters (BLS Ltd, Budapest, Hungary). Heterozygotes and homzygotes were distinguished by PCR genotyping for the wildtype allele using primers listed in Supplementary Table S1.

Wildtype C57BL/6J mice were used for MAPK western blots, estradiol measurements, and measurements of NEBD and ovulation. For most of these experiments, the wildtype mice were purchased from The Jackson Laboratory; a few wildtype mice were from the breeding colonies for the lines expressing Ca\(^{2+}\) sensors. All experiments with mice were performed at the University of Connecticut Health Center, and all animal protocols were approved by the University of Connecticut Health Center Animal Care Committee.

**Isolation and culture of follicles**

Follicles of the indicated sizes were dissected from prepubertal (24–27 day old) mice, and cultured on Millicell organotypic membranes (Merck Millipore, Cork, Ireland; PICMORG50) in MEMα medium (12 000–022, Invitrogen) with 25 mM NaHCO\(_3\), 75 μg/ml penicillin G, 50 μg/ml streptomycin, a mixture of 5 μg/ml insulin, 5 μg/ml transferrin, and 5 ng/ml selenium (Sigma-Aldrich, St. Louis, MO, #H1884), and 3 mg/ml bovine...
serum albumin (MP Biomedicals, #103 700). Where indicated, 1 nM FSH was included in the medium. To reduce Ca\(^{2+}\) in the medium, ETGA was added, and the resulting free Ca\(^{2+}\) concentrations were calculated using MaxChelator (https://somapp.ucdmc.ucdavis.edu/pharmacology/bers/maxchelator/downloads.htm) [31].

Follicles were used for experiments 24–30 h after isolation. Highly purified ovine FSH (APF7558C) and ovine LH (oLH-26) were obtained from A.F. Parlow (National Hormone and Peptide Program, Torrance, CA). The follicles, which were spheres when dissected, flattened to disks after culture on the Millicell membrane, thus facilitating imaging. Diameters described in the text refer to measurements at the time of dissection, and do not include the residual theca layer. For determining meiotic resumption in response to LH, follicle-enclosed oocytes were checked hourly for the loss of the nucleolus and nuclear envelope.

Confocal imaging

For confocal microscopy, follicles were placed in a 100 μl drop of medium in the channel of a “μ-slide” that connects two ports (ibidi GmbH, Martinsried, Germany, #80 176 custom ordered without adhesive; see [6]). Slides with a channel height of 100 μm (ibidi custom order) were used for follicles 140–250 μm in diameter; 290–360 μm follicles were placed in a 200 μm-deep slide. A thin layer of silicone grease was applied to the outer edge of the slide and a glass coverslip (ibidi # 10 812) was placed on the silicone to gently immobilize the follicle in the channel. FSH, LH, or control medium was applied by perfusing 200 μl of the solution through the channel by way of the ports. For recordings at 1–6 h after LH treatment, LH was applied to the follicles on Millicell membranes; just before imaging, follicles were transferred to a μ-slide in medium containing LH.

Follicles were imaged on a Zeiss LSM 5 Pascal confocal microscope using a C-Apochromat 40X/1.2 numerical aperture objective with Immersol W immersion medium (Carl Zeiss Microscopy). Twitch-2B CFP was excited using a 440 nm laser (Toptica Photonic, Victor, NY) and an HQ535/50M, respectively) were from Chroma Technology (Rocktonics, Victor, NY) using a power range of 1–5%. The dichroic mirror GCaMP6s was imaged using a 488 nm laser and an IRDye800CW filter (Rockingham, VT). GCaMP6s was imaged using a 488 nm laser and an HQ525/50M emission filter. A warm air blower (Nevtek ASI 400, Burnsville, VA) was used to maintain a stage temperature of 32–35 °C. For Twitch-2B, the pinhole was fully open (13 μm optical section); for GCaMP6s recordings, a 5 μm optical section was used. 12-bit scans at 512 × 512 resolution were collected every 10 s for up to 50 min. Background correction was applied by subtracting the averaged autofluorescence of 3–5 wildtype follicles imaged under identical conditions. Because ~28% of the light collected by the YFP emission filter is actually emitted by CFP, we subtracted 28% of the background-subtracted YFP intensity before calculating the CFP/YFP ratio.

RNA sequencing data analysis

Transcriptome data of mural granulosa cells from 2-month-old C57BL/6J mice [32] in FASTQ format were downloaded from the European Nucleotide Archive (ENA; https://www.ebi.ac.uk/ena). Sequence alignments were performed using the RNA STAR tool [33] within the Galaxy platform [34]. Reads were aligned to the mouse reference genome (GRCm38, a.k.a. mm10). Gene model for splice junctions, in GTF file format, was obtained from ENSEMBL ftp site (release 92). The GTF file was filtered to contain only entries with the “gene_biotype” value set to “protein_coding” in the “attributes” field. To calculate gene expression, we counted the numbers of reads aligned to exons using featureCounts [35] version 1.6.0.6 from within the Galaxy platform, with the value of “minimum bases of overlap” set to 30. To account for the depth of sequencing among datasets, we normalized count expression data to counts per million (CPM) [36] by using the formula $CPM = 10^6 \times C / T_s$, where $CPM$ is the CPM value for the gene $i$, $C$ is the number of counts reported by featureCounts, and $T_s$ is the total number of reads in the sample aligned to the genome. To identify all genes encoding Ca\(^{2+}\) channels, gene symbols for all mouse genes annotated to “GO:00 15085: calcium ion transmembrane transporter activity” were downloaded from Mouse Genome Informatics [37] (130 genes, downloaded on 09/05/2018). This list was edited to include only those genes encoding plasma membrane proteins that transport Ca\(^{2+}\). Ca\(^{2+}\) channels in organelles, Ca\(^{2+}\) channel regulatory proteins, and TRP channels that are not significantly permeable to Ca\(^{2+}\) [38] were removed from the list.

Western blotting

Western blots for quantifying the Twitch-2B concentration were probed with a primary antibody against GFP (Cell Signaling Technology, Beverly, MA; #2555); this antibody also recognizes CFP and YFP. The Epac2-camps protein that was used as a standard for these blots has a similar CFP and YFP-containing structure as Twitch-2B, and > 90% purity [39]. Western blots for detecting MAP kinase phosphorylation were probed with primary antibodies against phospho-MAPK1/3 (Thr202/Tyr204) and total MAPK1/3 (Cell Signaling Technology, #4370 and #4696, respectively). MAPK1 is also known as ERK2 or p42MAPK, and MAPK3 is also known as ERK1 or p44MAPK. The antibody used to detect PDE1A was from Proteintech (Rosemont, IL, #12 442-2-AP). For all western blots except Supplementary Figure S4, antibody binding was detected using fluorescent secondary antibodies (LI-COR Biosciences, Lincoln, NE; IRDye800CW and IRDye680RD) and a LICOR Odyssey imaging system. The secondary antibody for Supplementary Figure S4 was conjugated to horseradish peroxidase (Santa Cruz Biotechnology, Dallas, TX) and detected with ECL Prime (GE Healthcare, Chicago, IL) and a CCD camera (G: BOX Chemi XT4, Syngene, Frederick, MD). Further antibody details are included in Supplementary Table S2. Signal intensities were measured using ImageJ (https://imagej.nih.gov/ij/).

Sources of reagents

YM-254 890 was obtained from Wako Chemicals (Richmond, VA). EGTA, cadmium chloride, nickel chloride, and nifedipine were from Sigma-Aldrich. ELISA kits for measurement of 17β-estradiol were from Cayman Chemical (Ann Arbor, MI).

Statistics

Analyses were conducted as described in the figure legends using Prism 6 (GraphPad Software, Inc, La Jolla, CA). All values indicate mean ± standard error of the mean (SEM). Multiple t-tests (either with or without ANOVA) were corrected for multiple comparisons using the Holm-Sidak correction when comparing all groups to each other, or the Dunnett correction when comparing all groups to a single control.
Results and discussion

Measurement of an FSH-induced increase in Ca\(^{2+}\) in the granulosa cells of intact ovarian follicles expressing the Twitch-2B FRET sensor

Using Twitch-2B expressing follicles ranging in diameter from \(\sim 140 \mu m\) (preantral) to \(\sim 320 \mu m\) (fully grown antral), we measured Ca\(^{2+}\) levels before and after addition of FSH. The follicles were imaged by confocal microscopy, with the focus on the oocyte equator (Figure 1A). Twitch-2B fluorescence was seen in the granulosa cells, but was too low to be useful for measurements in the oocyte. In some of the smaller follicles, the fluorescence was uniform throughout the granulosa cells (Figure 1A), although in others, it was dimmer in the interior granulosa layers. In larger follicles, the fluorescence was consistently dimmer in the interior layers (see Figure 4A). For this reason, measurements were made from the outer 25 \(\mu m\) region of granulosa cell layer, except as indicated. Twitch-2B was also present in the residual theca/blood vessel layer surrounding the follicle, and was expressed at a higher level than in the granulosa cells. The amount of adhering theca was variable (compare Figures 1A and 4A). Because the theca layer was not intact, we did not investigate FSH-induced Ca\(^{2+}\) changes in this region.

Binding of Ca\(^{2+}\) to Twitch-2B increases FRET between CFP and YFP, such that an increase in the YFP/CFP emission ratio measured after CFP excitation indicates an increase in free Ca\(^{2+}\); the EC\(_{50}\) of Twitch-2B is \(\sim 200 \text{nM}\) [28]. In response to perfusion of 1 nM FSH, YFP emission in the granulosa cells increased and CFP emission decreased (Figure 1B, C), indicating an increase in Ca\(^{2+}\). The Ca\(^{2+}\) rise began several minutes after FSH application. Ca\(^{2+}\) levels reached a peak at about 10 min after the initial FSH exposure, and remained above baseline for at least another 10 min.

The FSH-induced Ca\(^{2+}\) increase occurs at a physiological concentration of FSH, in follicles of different sizes, and for preantral follicles, throughout the entire granulosa cell compartment

In Twitch-2B-expressing follicles, a concentration of 1 nM FSH was sufficient to elevate Ca\(^{2+}\) to an almost maximal level, while no rise in Ca\(^{2+}\) was seen with 0.1 nM FSH (Figure 1D). Follicles of all size classes tested responded similarly to 1 nM FSH (Figure 1E). The 1 nM concentration of FSH required to stimulate a rise in Ca\(^{2+}\) correlates well with the concentration of FSH needed to optimally stimulate follicular development in our culture system. In this system, 0.3 nM FSH causes \(\sim 80\%\) of follicles to acquire the ability to resume meiosis in response to LH, whereas 1 nM FSH causes 100\% of follicles to become LH responsive [7]. During the reproductive cycle, the FSH concentration in mouse serum reaches a peak of \(760 \text{ng} / \text{mL}\) on the second day of estrus [41, 42].

The measurements described above were made in the outer 25 \(\mu m\) of the granulosa cell layer, due to low expression of the Ca\(^{2+}\) sensor in the follicle interior. However, for some of the smaller follicles (7 of the 23 in the 140–250 \(\mu m\) diameter range, in Figure 1E), Twitch-2B fluorescence in the inner regions of the follicle was sufficient to measure. In these follicles, the FSH-induced Ca\(^{2+}\) rise had an approximately similar amplitude and time course in all regions of the granulosa cell compartment (Figure 1F).

Lack of Ca\(^{2+}\) buffering by the Twitch-2B sensor

Expression of the Twitch-2B sensor could conceivably buffer cytosolic Ca\(^{2+}\), reducing the signal amplitude. We assessed this possibility by comparing mice heterozygous or homozygous for Twitch-2B. CFP fluorescence was about two-fold higher in homozygous follicles (Supplementary Figure S2A), reflective of Twitch-2B protein expression levels. However, the baseline YFP/CFP ratio and the peak ratio in response to FSH were not different between heterozygous and homozygous follicles (Supplementary Figure S2B), indicating that Twitch-2B expression did not alter basal Ca\(^{2+}\) levels or attenuate the FSH-induced Ca\(^{2+}\) increase. Thus the \(\sim 20 \mu M\) cytosolic concentration of the Twitch-2B sensor in homozygous follicles (see Materials and Methods) is not a significant buffer, consistent with previous determinations that \(\sim 100 \mu M\) of the Ca\(^{2+}\) buffer BAPTA is required to blunt Ca\(^{2+}\) rises in other cells [41, 42].

The FSH-induced Ca\(^{2+}\) increase occurs uniformly in all cells in the outer granulosa cell region, as detected in follicles expressing the GCaMP6s sensor

To test whether Ca\(^{2+}\) increases uniformly in all cells in the outer 25 \(\mu m\) granulosa region, we imaged the Ca\(^{2+}\) increase using follicles from mice expressing the GCaMP6s sensor [27], which shows increased fluorescence when Ca\(^{2+}\) is bound; the EC\(_{50}\) for GCaMP6s is \(\sim 140 \text{nM}\) [43]. GCaMP6s is not a ratiometric indicator, so is less useful for comparing different follicles, but it has the advantage of allowing direct visualization of the spatial distribution of Ca\(^{2+}\) within a single follicle. As seen with Twitch-2B, GCaMP6s fluorescence was fairly uniform in the granulosa cells of smaller follicles, although undetectable in the oocyte (Figure 2A), but was restricted to the outer mural granulosa cells in larger follicles (see Figures 5A and 6A below).

Following perfusion with 1 nM FSH, Ca\(^{2+}\) increased uniformly throughout the outer granulosa cell region, and all cells had similar Ca\(^{2+}\) dynamics (Figure 2A, B and supplementary movie 1). The kinetics of the Ca\(^{2+}\) increase and subsequent decrease were similar to those observed with Twitch-2B (compare Figures 1C and 2B).

Like Twitch-2B, GCaMP6s was also expressed in the theca layer, and its fluorescence there was brighter than in the granulosa cells (see Figures 2A, 5A, and 6A). It is unknown if the higher fluorescence in the theca was due to higher expression of the sensor protein or to higher basal Ca\(^{2+}\).

The FSH-induced Ca\(^{2+}\) increase is due to influx from the extracellular solution

To investigate if the FSH-induced Ca\(^{2+}\) increase is due to Ca\(^{2+}\) influx from the extracellular solution, we added 2.0 mM EGTA to the medium, which contained 1.8 mM CaCl\(_2\), thus lowering extracellular free Ca\(^{2+}\) to \(\sim 0.002 \text{mM}\) (see Materials and Methods). After 20 min, we perfused FSH onto the follicle while measuring the Twitch-2B signal. Under these conditions, FSH did not cause a detectable increase in Ca\(^{2+}\) in the granulosa cells (Figure 3A, B). To investigate if the FSH-induced Ca\(^{2+}\) increase results from Ca\(^{2+}\) influx, we added 0.01 mM EGTA to the medium, which contained 3.4 mM CaCl\(_2\). Consistent with this conclusion, exposure to 10 \(\mu M\) YM-254 890, which inhibits signaling by G\(_{q}\)-family G-proteins [44, 45; see Figures 4E and 6A, B below] and thus inhibits Ca\(^{2+}\)
FSH and LH-induced Ca\textsuperscript{2+} rises in ovarian follicles, 2019, Vol. 101, No. 2

Figure 1. FSH increases intracellular Ca\textsuperscript{2+} in the mural granulosa cells of intact follicles, as detected by Twitch-2B. (A) Representative transmitted light and CFP + YFP fluorescence images of a follicle after a 28-h culture on a Millicell membrane. Prior to flattening on the membrane, the follicle measured \(\sim 180\ \mu\text{m}\) in diameter. Note that the residual theca cells that surround the follicle and that were not removed by dissection show higher fluorescence intensity than the granulosa cells, indicating the presence of more Twitch-2B protein in the theca cells. (B) Representative traces showing changes in YFP and CFP fluorescence before and after perfusion with control medium (MEM\(\alpha\)) or 1 nM FSH. Following FSH perfusion, the two channels change in opposite directions, indicating an increase in FRET (same follicle as A). (C) Representative trace showing the YFP/CFP ratio before and after treatment with 1 nM FSH (same follicle as B). The increase in YFP/CFP ratio indicates that 1 nM FSH induces a transient Ca\textsuperscript{2+} increase in the granulosa cells. (D) Both 1 nM and 100 nM FSH induce Ca\textsuperscript{2+} increases of similar magnitude. Peak YFP/CFP ratios during perfusion of control medium (MEM\(\alpha\)) and the indicated concentrations of FSH. Follicle diameters at the time of isolation from the ovary were 140–250 \(\mu\text{m}\). (E) The Ca\textsuperscript{2+} response to 1 nM FSH is similar in follicles of different sizes. Peak YFP/CFP ratios before and after perfusion of 1 nM FSH, for follicles of the indicated diameters (those in the 140–180 \(\mu\text{m}\) and 220–250 \(\mu\text{m}\) groups are the same follicles as in A). Numbers within the bars indicate the number of follicles tested. Different letters indicate significant differences \((P < 0.05)\) after one-way ANOVA (D) or two-way ANOVA (E), followed by \(t\)-tests with the Holm-Sidak correction for multiple comparisons. For (E), lowercase letters indicate comparisons among MEM\(\alpha\) groups; uppercase letters reflect comparisons between groups treated with FSH. All values represent mean \(\pm\) s.e.m. (F) The FSH-induced Ca\textsuperscript{2+} rise is similar in different regions of preantral follicles. Traces show fluorescence intensity as a function of time for 3 concentric regions of a representative follicle: in the outer 25 \(\mu\text{m}\) (green), the middle 25–50 \(\mu\text{m}\) (magenta), and the inner 25 \(\mu\text{m}\) (yellow). The follicle used for these measurements was 160 \(\mu\text{m}\) in diameter at the time of isolation.

release from the endoplasmic reticulum, did not prevent the Ca\textsuperscript{2+} rise in response to FSH (Figure 3A, B).

To identify candidate ion channels potentially mediating the FSH-induced Ca\textsuperscript{2+} influx, we analyzed gene expression data from next generation sequencing of mouse mural granulosa cell mRNA [32] (Supplementary Table S3). Among the genes encoding plasma membrane Ca\textsuperscript{2+} permeable channels, the most highly expressed was \textit{Trpm7}, followed by 2 voltage-gated Ca\textsuperscript{2+} channels: \textit{Cacna1b} (T type) and \textit{Cacna1a} (P/Q type). Other plasma membrane Ca\textsuperscript{2+} permeable channels, including a voltage-gated L type channel, a glutamate receptor, a purinergic receptor, and pannexin 1 were expressed at somewhat lower levels. In an attempt to inhibit some of these channels, we tested several voltage-sensitive Ca\textsuperscript{2+} channel blockers, Cd\textsuperscript{2+}, Ni\textsuperscript{2+}, and nifedipine [46]. At the concentrations tested, none inhibited the FSH-induced Ca\textsuperscript{2+} increase (Supplementary Figure S3), which is not surprising because multiple
channel types were detected in RNAseq transcriptome data of mural granulosa cells (Supplementary Table S3), likely obscuring suppression of Ca\textsuperscript{2+} influx. The possible role of TRPM7 channels, for which specific inhibitors are not yet available [47], remains to be investigated, as does the question of how activation of the FSH receptor results in opening of these or other Ca\textsuperscript{2+} channels.

The function of the FSH-induced Ca\textsuperscript{2+} increase is unknown

Previous studies of isolated rat granulosa cells have indicated that FSH-induced phosphorylation of the mitogen-activated protein kinases MAPK1 and MAPK3 depends on extracellular Ca\textsuperscript{2+} [16]. MAPK1/3 phosphorylation is of particular interest because it is essential for the FSH-induced increase in synthesis of aromatase, which catalyzes the synthesis of estradiol [17]. Therefore, we investigated the effect of reducing extracellular Ca\textsuperscript{2+} on the FSH-induced phosphorylation of MAPK1/3 and synthesis of estradiol in mouse follicles. However, suppression of the FSH-induced Ca\textsuperscript{2+} rise by addition of 1.6 mM EGTA to the medium did not inhibit FSH-induced MAPK1/3 phosphorylation (Figure 3C) or estradiol synthesis (Figure 3D). It also did not prevent the FSH-induced acquisition of the ability to resume meiosis in response to LH (Figure 3E). Our findings indicate that the FSH-induced Ca\textsuperscript{2+} rise is not required for several biological functions. Whether the Ca\textsuperscript{2+} rise is part of a back-up system for these functions, or whether it regulates other functions such as FSH-induced granulosa cell proliferation or suppression of apoptosis, remains to be investigated.

LH causes persistent Ca\textsuperscript{2+} oscillations in the granulosa cells of intact ovarian follicles

To investigate whether LH increases Ca\textsuperscript{2+} in the granulosa cells of intact follicles, we isolated follicles with diameters of 290–360 \( \mu \)m, and cultured them for 24–30 h in the presence of 1 nM FSH to induce expression of LH receptors. In follicles expressing Twitch-2B, the fluorescence signal was strong in the outer mural granulosa cells, but in the inner mural granulosa cells, cumulus cells, and oocyte, the signal was too weak to be useful (Figure 4A). Therefore, measurements were made from the outer 25 \( \mu \)m layer of granulosa cells. Perfusion of 10 nM LH caused a barely detectable Ca\textsuperscript{2+} increase, as indicated by a small increase in the YFP/CFP emission ratio of Twitch-2B (Figure 4B, C, D). In response to subsequent perfusion of 300 nM LH, Ca\textsuperscript{2+} began to increase immediately, reached
FSH and LH-induced Ca\textsuperscript{2+} rises in ovarian follicles, 2019, Vol. 101, No. 2

Figure 3. The FSH-induced Ca\textsuperscript{2+} increase in granulosa cells of intact follicles requires extracellular Ca\textsuperscript{2+}, but MAPK phosphorylation, 17\beta-estradiol production, and LH-induced NEBD occur independently of the Ca\textsuperscript{2+} increase. (A) Representative traces showing no FSH-induced Ca\textsuperscript{2+} increase in follicles (220–250 \(\mu\)m diameter) in media with low extracellular Ca\textsuperscript{2+}, and no effect of the G\textsubscript{q}-family G-protein inhibitor YM-254 890 (10 \(\mu\)M) on the FSH-induced Ca\textsuperscript{2+} increase. MEM\textsubscript{a}, which contains 1.8 mM CaCl\textsubscript{2}, was mixed with either 2 mM EGTA (\(\sim 0.002\) mM free Ca\textsuperscript{2+}; upper panel), or 1.6 mM EGTA (\(\sim 0.2\) mM free Ca\textsuperscript{2+}; middle panel). Follicles were pre-incubated for \(\sim 20\) min in these EGTA solutions, or for 60 min in YM-254 890 (lower panel), before addition of FSH. (B) Peak YFP/CFP ratios before and after perfusion of 1 nM FSH in the presence of varying extracellular Ca\textsuperscript{2+} concentrations, buffered by EGTA addition as in A, or in the presence of YM-254 890 (10 \(\mu\)M). The ability of YM-254 890 to inhibit LH-induced Ca\textsuperscript{2+} elevation (see Figures 4E and 6A, B below) served as a positive control for the permeability of this inhibitor. Open bars indicate the peak YFP/CFP ratio after MEM\textsubscript{a} perfusion; filled bars indicate peak YFP/CFP ratio following FSH perfusion. Following two-way ANOVA, the peak ratios following FSH perfusion in each group were compared to the control (green) bar by \(t\)-tests with the Dunnett correction for multiple comparisons; *** indicates \(P < 0.0001\), n.s. indicates \(P > 0.05\). None of the peak ratios measured during MEM\textsubscript{a} perfusion (open bars) were significantly different from the control (all \(P > 0.05\)). (C) FSH-induced MAPK phosphorylation occurs independently of extracellular Ca\textsuperscript{2+}. Left: Representative western blot for phospho- and total MAPK in lysates of 180–250 \(\mu\)m follicles incubated for 20–30 min in medium with either 1.8 mM or 0.2 mM Ca\textsuperscript{2+} (prepared as in A), and then for 20 min in these same media with or without 1 nM FSH. Right: Ratio of phospho-/total MAPK from 3 independent experiments; n.s. indicates \(P > 0.05\) by unpaired \(t\)-test. (D) FSH-induced estradiol production occurs independently of extracellular Ca\textsuperscript{2+}. 290–360 \(\mu\)m follicles were incubated with 1 nM FSH in media containing either 1.8 mM or 0.2 mM Ca\textsuperscript{2+}. Medium samples were collected at the indicated times for estradiol analysis. Each point represents three experiments using 14–20 follicles for each treatment. (E) FSH-induced acquisition of LH responsiveness occurs independently of extracellular Ca\textsuperscript{2+}. 290–360 \(\mu\)m follicles were incubated for 24 h with 1 nM FSH in media with either 1.8 mM or 0.2 mM Ca\textsuperscript{2+}; 10 nM LH was then added to each dish and the time course of NEBD was determined. Each point represents three experiments using 12–19 follicles for each condition. Same legend as in (D). Values in (B-E) represent mean ± s.e.m.

We next tested whether the Ca\textsuperscript{2+} elevation in response to 10 nM LH might be more evident using GCaMP6s, which has an EC\textsubscript{50} of \(\sim 140\) nM vs \(\sim 200\) nM for Twitch-2B. GCaMP6s is also more sensitive because Ca\textsuperscript{2+} causes a proportionately larger change in fluorescence intensity than that seen with Twitch-2B (compare Figures 1B and 2B, and Figures 4B and 5B below). When a follicle expressing GCaMP6s was exposed to 10 nM LH, some individual follicles showed a peak at about 5 min, and remained above baseline for at least another 5 min (Figure 4B, C, D). The peak concentration of LH in the serum during the mouse reproductive cycle is about 1 nM [48, 49], but 10 nM is the minimum concentration of ovine LH needed to cause meiotic resumption in all follicles under our experimental conditions [7], perhaps related to use of LH from a different species.
The LH-induced Ca$^{2+}$ increases require the activity of a $G_{q}$-family G-protein

The LH-induced Ca$^{2+}$ elevations in the granulosa cells were blocked by 10 μM of the G$_{q}$-family G-protein inhibitor YM-254 890 (Figures 4E and 6A, B; supplementary movie S6). 10 μM YM-254 890 inhibits signaling by G$_{q}$-family G-proteins (G$_{q}$, G$_{11}$, and G$_{14}$), but not by other G-proteins (G$_{i}$, G$_{o}$, G$_{13}$), or by voltage-gated or ATP-gated Ca$^{2+}$ channels [44, 45]. These data indicate that, unlike the FSH-induced Ca$^{2+}$ rise, the LH-induced Ca$^{2+}$ oscillations are most likely initiated by IP$_{3}$-induced Ca$^{2+}$ release from the endoplasmic reticulum. Consistently, previous studies have shown that LH induces IP$_{3}$ production in isolated granulosa cells of rat [22] and mouse [51].

Inhibition of G$_{q}$-family G-proteins does not inhibit LH-induced meiotic resumption, but does delay ovulation

Previous studies have suggested that an LH-induced Ca$^{2+}$ rise in the granulosa cells might contribute to causing meiotic resumption [18, 19]. However, inhibition of the LH-induced Ca$^{2+}$ oscillations with the G$_{q}$-family inhibitor YM-254 890 did not inhibit or delay meiotic resumption in mouse follicle-enclosed oocytes (Figure 6C). This result confirms a previous finding that G$_{q}$ family G-proteins are not required for meiotic resumption [51]. However, since the Ca$^{2+}$-activated cGMP phosphodiesterase PDE1 is expressed in mouse granulosa cells (Egbert et al., 2016, and Supplementary Figure S4), the LH-induced Ca$^{2+}$ rise would increase cGMP phosphodiesterase activity, and thus would contribute to decreasing cGMP. Therefore, while the Ca$^{2+}$ rise is not required for LH-induced meiotic resumption, it could be a component of a “failsafe” system that ensures that LH signaling lowers cGMP such that meiosis proceeds.

Inhibition of G$_{q}$ family G-proteins with YM-254 890 did have an inhibitory effect on LH-induced ovulation (Figure 6D). 50% of control follicles had ovulated by ~13 h after LH application, whereas in the presence of 10 μM YM-254 890, 50% ovulation did not occur until ~16 h. These results with isolated follicles confirm the inhibitory effect on ovulation that was seen in mice in which G$_{q}$ and G$_{11}$ expression in the granulosa cells was inactivated genetically [51]. Thus, the LH-induced Ca$^{2+}$ oscillations may signal together
FSH and LH-induced Ca\(^{2+}\) rises in ovarian follicles, 2019, Vol. 101, No. 2

Figure 5. LH induces Ca\(^{2+}\) oscillations in mural granulosa cells, as detected with GCaMP6s. (A) The left hand image shows a large antral follicle after 25-h culture in the presence of 1 nM FSH. The yellow box outlines an area for which enlarged images are shown at 8 time points: before LH (image 1), after perfusion of 10 nM LH (images 2–7), and after perfusion of 300 nM LH (image 8); scale bar = 25 μm. The yellow circle (10 μm in diameter) indicates a mural granulosa cell that undergoes Ca\(^{2+}\) oscillations in response to 10 nM LH. Calcium oscillations are also visible in several other mural granulosa cells. The green oval indicates theca cell that undergoes calcium responses in response to 10 nM LH. Supplementary movie S2 shows the entire time series from which these images were selected, and supplementary movie S3 shows another example. (B) Fluorescence intensity before and after LH perfusion, for the granulosa cell in (A) that is indicated by the yellow circle. Images were taken at 10-s intervals. Points in red correspond to the numbered images in (A). Representative of 4 follicles. (C) Ca\(^{2+}\) oscillations in the outer mural granulosa cells continue for at least 6 h after treatment with 10 nM LH. The graph shows the fluorescence intensity as a function of time for one such cell. Representative of two follicles each at 1, 2, and 4 h, and three follicles at 6 h after LH. Supplementary movie S4 shows an example at 2 h after LH, and supplementary movie S5 shows the full time series from which data shown in C were measured.

with cAMP to stimulate ovulation. Other possible functions of LH-induced Ca\(^{2+}\) oscillations, in both the granulosa and theca cells, remain to be investigated.

Supplementary data

Supplementary data are available at BIOLRE online.

**Supplemental Figure S1.** Estimate of Twitch-2B concentration in follicles, and normal LH responses of follicles from Twitch-2B homozygous mice. (A) Western blot to estimate the concentration of Twitch-2B protein in follicles (320–360 μm diameter) from homozygous (Tw/Tw) mice. 10 μg of follicle protein was separated by SDS-PAGE, in parallel with various amounts of a related YFP and CFP-containing protein (Epac2-camps, > 90% pure) that was used as a standard. (B) Ovarian follicles from homozygous (Tw/Tw) mice expressing the Twitch-2B sensor show a normal time course of NEBD (left) and a normal percentage of ovulation (right) in response to 10 nM LH. For (A, B), follicles were incubated on Millicell membranes for ~24 h with 1 nM FSH before use. Data in both panels represent the mean ± s.e.m. of 2–3 experiments with 12–19 follicles each.

**Supplemental Figure S2.** Follicles from Twitch-2B homozygous mice express approximately twice as much Twitch-2B sensor as heterozygotes, but both genotypes show similar increases in YFP/CFP ratio in response 1 nM FSH. (A) Follicles from mice homozygous for Twitch-2B are significantly brighter than those from heterozygous mice. CFP fluorescence values obtained during the baseline (MEMa) recording period were normalized to the laser power applied. (B) Peak YFP/CFP ratios before or after perfusion of 1 nM FSH are not different between follicles from heterozygous and homozygous Twitch-2B mice. Data for (A, B) are from the same follicles as 1 nM FSH bars in Figure 1D. Numbers within the bars indicate the number of follicles tested. *** indicates P < 0.001 by unpaired t-test; n.s. indicates P > 0.05 by unpaired t-test. All values represent mean ± s.e.m.

**Supplemental Figure S3.** The FSH-induced Ca\(^{2+}\) increase is not blocked by several inhibitors of voltage-gated Ca\(^{2+}\) channels. Peak
Figure 6. The Gq-family G-protein inhibitor YM-254 890 prevents Ca\textsuperscript{2+} oscillations in response to LH, and delays ovulation. Experiments were performed using follicles 290–360 μm in diameter that had been cultured for ~24 h in the presence of 1 nM FSH. (A, B) A follicle expressing GCaMP6s was pre-incubated with 10 μM YM-254 890 for 60 min before adding 10 nM LH. The yellow box outlines an area for which enlarged images are shown at four time points: before LH (image 1), after perfusion of 10 nM LH (images 2 and 3), and after perfusion of 300 nM LH (image 4); scale bar = 25 μm. The yellow circle (10 μm in diameter) indicates a mural granulosa cell for which the fluorescence intensity is graphed in B. Supplementary movie S6 shows the entire time series from which these images were selected. Representative of 3 follicles. (C, D) Inhibition of Gq-family G-proteins by preincubation of follicles with 10 μM YM-254 890 for 60 min before addition of 10 nM LH does not inhibit NEBD, but does delay ovulation. Graphs in C and D show the mean ± s.e.m of 3 and 4 experiments, respectively, with 10–18 follicles each. Data in (D) were analyzed by repeated measures two-way ANOVA, with the Holm-Sidak correction for multiple comparisons applied to the t-tests between the DMSO and YM-254 890 groups at each time point; ** indicates \( P < 0.01 \) and ++++ indicates \( P < 0.0001 \).

YFP/CFP ratios before and after perfusion of 1 nM FSH in the presence of 200 μM Cd\textsuperscript{2+}, 200 μM Ni\textsuperscript{2+}, or 100 μM nifedipine. Open bars indicate the peak YFP/CFP ratio during MEMa perfusion; filled bars indicate peak YFP/CFP ratio after FSH perfusion. For all treatment groups, the peak ratios following FSH perfusion were compared to the control (green) bar by unpaired t-tests; n.s. indicates \( P > 0.05 \). All values represent mean ± s.e.m.

Supplemental Figure S4. Western blot showing the presence of PDE1A in mouse granulosa cells. 2 μg of granulosa cell protein from B6SJL/J mice was separated by SDS-PAGE and immunoblotted for PDE1A. Mice were injected at 22 days old with 5 IU equine chorionic gonadotropin. 46 h later, the ovaries were removed and large antral follicles were punctured with needles to release granulosa cells.

Supplemental Table S1. PCR primers used for detecting the wild-type allele for genotyping of Twitch-2B and GCaMP6s mice.

Supplemental Table S2. Antibodies used for western blotting.

Supplemental Table S3. Ca\textsuperscript{2+} permeable plasma membrane channels identified by RNA sequencing of mouse mural granulosa cells.
(average of 2 samples from 2-month old C57BL/6 mice; see Materials and Methods). The right-hand column indicates CPM and SEM for each gene. Genes with average CPM ≥ 25 are highlighted.

Supplemental Movie S1. FSH-induced Ca²⁺ increase in a follicle expressing GCaMP6s. The movie shows the time series of images of the follicle region shown in Figure 2A during sequential perfusion with MEMa (Control) and 1 nM FSH. Images were taken every 10 s, and are displayed at 10 frames per second (fps). Note that the theca cells outside of the follicle show a transient Ca²⁺ increase in response to the mechanical stimulus during perfusion, independent of FSH. Time series is representative of four follicles.

Supplemental Movie S2. LH-induced Ca²⁺ increase in a follicle expressing GCaMP6s. The movie shows the time series of images of the follicle region shown in Figure 5A during sequential perfusion with MEMa (Control), 10 nM LH, and 300 nM LH. Images were taken every 10 s, and are displayed at 10 fps. Three flat-shaped theca cells are seen adhering to the follicle and are brighter than the granulosa cells, indicating a higher level of Twitch-2B expression. These cells also showed Ca²⁺ oscillations in response to LH. Time series is representative of four follicles.

Supplemental Movie S3. LH-induced Ca²⁺ increase in a follicle expressing GCaMP6s. The movie shows the time series of images of another representative follicle with a larger field of view, perfused sequentially with MEMa (Control), 10 nM LH, and 300 nM LH. Images were taken every 10 s, and are displayed at 10 fps. A layer of flat theca cells is present, and as seen in Movie S2, showed Ca²⁺ oscillations in response to LH. Time series is representative of two follicles.

Supplemental Movie S4. Ca²⁺ oscillations persist 2 h after treatment with 10 nM LH in the granulosa cells of a follicle expressing GCaMP6s. Images were taken every 10 s, and are displayed at 10 fps. Time series is representative of two follicles.

Supplemental Movie S5. Ca²⁺ oscillations persist 6 h after treatment with 10 nM LH in the granulosa cells of a follicle expressing GCaMP6s. The movie shows the time series of the follicle shown in Figure 5C. Images were taken every 10 s, and are displayed at 10 fps. Time series is representative of three follicles.

Supplemental Movie S6. Inhibition of the LH-induced Ca²⁺ increase by inhibition of Gq-family G-proteins in a follicle expressing GCaMP6s. The movie shows the time series of images of the follicle region shown in Figure 6A. The follicle was preincubated for 1 h with 10 μM YM-254 890 (Gq-family Gprotein inhibitor), then perfused sequentially with 10 μM YM-254 890, 10 μM YM-254 890 + 10 nM LH, and 10 μM YM-254 890 + 300 nM LH. Images were taken every 10 s, and are displayed at 10 fps. Time series is representative of three follicles.

Acknowledgements

We thank Rachael Norris and Lea Shuhaibar for their participation in initiating this project using earlier Ca²⁺ measurement methods, Siu-Pok Yee and Deborah Kaback for their expertise and advice on mouse genome modification and colony maintenance, and Tracy Uliaz, Giulia Vigone, Mary Hunzicker-Dunn, Aylin Hanyaloglu, Lixia Yue, and Paul Brehm for useful discussions. The Tolias lab thanks Zheng Huan Tan for colony management.
